Mapping of poynting flux of dispersive Alfvén waves

N. Singh
Department of Electrical and Computer Engineering, University of Alabama, Huntsville, Al 35899, USA

Abstract. We theoretically determine the group velocity vector of Alfvén waves having narrow structures transverse to an ambient magnetic field. The theory is used to determine the width of such wave structures as they propagate downward from high altitudes where satellite observations are normally made. We predict that for very narrow structures in the regime of inertial and kinetic Alfvén waves the Poynting flux maps with altitude r as $S(r) \sim B(r)^{1/2}$, in contrast to the commonly assumed mapping relation $S(r) \sim B(r)$, where B is the magnetic field intensity. While the theory is used to determine the width of such wave structures as they propagate downward from high altitudes where satellite observations are normally made. We predict that for very narrow structures in the regime of inertial and kinetic Alfvén waves the Poynting flux maps with altitude r as $S(r) \sim B(r)^{1/2}$, in contrast to the commonly assumed mapping relation $S(r) \sim B(r)$, where B is the magnetic field intensity.

1. Introduction

There are now several satellite measurements of Alfvén waves and their power densities, the Poynting flux $S$ (Wygant et al., 2000, 2002; Domback et al., 2005; Angelopoulos et al., 2002; Chaston et al., 1999). While mapping the measured $S$ along the geomagnetic field lines, it is common to assume that $S(r) \sim B(r)$, where B is the magnetic field intensity and r is the geocentric distance. This assumption holds good only for non-dispersive Alfvén waves with parallel wave number $k_\parallel = 0$ having scales transverse to the geomagnetic field of the order of the geophysical scale lengths. The measured waves are often narrow structures transverse to B, implying not only relatively large values of $k_\perp$, but also a broad spectrum of $k_\parallel$. Such waves are dispersive and the propagation of energy depends on both parallel and perpendicular components of the group velocity vector $V_g$ (Stasiewicz et al., 1997; Singh, 1999). The mapping using $S(r) \sim B(r)$ tacitly assumes that $V_g \sim 0$. The purpose of this paper is to theoretically explore the parametric behavior of $V_g$ depending on the plasma parameters, such as the plasma density, and electron and ion temperatures as the geocentric altitude r varies covering the satellites such as FAST, Polar and Geotail. Fortunately, there are measurements of $S$ during magnetic conjunctions between FAST and Polar (Domback et al., 2005) and also between Polar and Geotail (Angelopoulos et al., 2003) to check the theoretical predictions. We specifically show that for very narrow structures conforming to the dispersion relation of inertial and kinetic Alfvén waves, the mapping is according to $S(r) \sim B(r)^{1/2}$.

2. Group velocity for dispersive Alfvén waves

A useful dispersion relation for Alfvén waves with non-zero $k_\perp$ is given by (Lysak and Lotko, 1996)

$$\omega = k_\parallel V_A[(1 + (k_\perp \rho_a)^2)/(1 + (k_\parallel \lambda_a)^2)]^{1/2},$$

where $k_\parallel$ is the parallel component of wave vector $k$, $V_A$ is the Alfvén velocity, $\rho_a = \rho_i \times (0.75+T_e/T_i)^{1/2}$, $\rho_i$ is the ion Larmor radius, $T_e$ and $T_i$ are the electron and ion temperatures, and the electron skin depth $\lambda_a = C/\omega_{pe}$ with C and $\omega_{pe}$ as the velocity of light and the electron plasma frequency, respectively. The parallel ($V_{g\parallel}$) and perpendicular ($V_{g\perp}$) components of the group velocity vector $V_g$, given by $V_g = \partial \omega/\partial k_\parallel$ and $V_{g\perp} = \partial \omega/\partial k_\perp$, are

$$V_{g\parallel} = V_A[(1 + k_\parallel^2 \rho_a^2)/(1 + k_\perp^2 \lambda_a^2)]^{1/2},$$

$$V_{g\perp} = V_A k_\parallel [(1 + k_\perp^2 \rho_a^2)/(1 + k_\perp^2 \lambda_a^2)]^{1/2} G(k_\parallel),$$

$$G(k_\parallel) = \rho_a^2 [(1 + k_\perp^2 \lambda_a^2)^{-1} - \lambda_a^2][1 + k_\perp^2 \rho_a^2][1 + k_\perp^2 \lambda_a^2]^2.$$  

For the angle $\theta$ made by $V_g$ from $B_\perp$ given by $\tan(\theta) = V_{g\perp}/V_{g\parallel}$ and using $\tan(\theta) = 0$ for small $\theta$, we have

$$\theta = (\omega/\Omega_p)(m/M)^{1/2} k_\perp [(1 + k_\parallel^2)/(1 + k_\perp^2 \alpha^2)]^{1/2} \times \alpha^2 (1 + k_\parallel^2 \alpha^2)^{1/2} (1 + k_\parallel^2)^{1/2}.$$

Note that in writing (5) we have expressed $k_\perp$ in units of $k_\perp = 1/\lambda_a$, that is, $k_\perp \lambda_a \rightarrow k_\parallel$, and $\alpha = \rho_a/\lambda_a$. The parameter $\alpha$ is an important quantity; it determines the nature of the dispersion whether the wave is inertial (IA) or kinetic (KA) Alfvén wave (Singh, 1999). Physically $\alpha^2$ is related to the plasma $\beta$, $\alpha^2 = (\rho_a/\lambda_a)^2 = (M/m)[(0.75+T_e/T_i)(\omega_{pe}/\Omega_p)^2/(V_{eff}/V_A)^2 - (M/m)\beta]$, where $\beta$ is the ratio of plasma kinetic to magnetic energy density. M and m are the ion and electron mass respectively. We find that when $\alpha^2 < 1$ or $V_A \sim V_{eff}$, the effective electron thermal velocity, or equivalently $\beta \sim m/M$, $\theta \sim 0$. When $\alpha^2 < 1$, $\theta$ is negative and it implies that the IA waves in this regime are backward wave in the direction...
transverse to $B_s$. On the other hand when $\alpha^2 \gg 1$, the KA waves have $\theta > 0$. Fig. 1 shows a series of curves showing $\theta(k_\perp)$ for several values of $\alpha$. As expected, there are two distinct families of curves for the KA and IA waves. KA waves have $\theta > 0$ while IA waves have $\theta < 0$. For the IA waves the curve for $\alpha=0.01$ is like that in a cold plasma (Singh, 1999). As $\alpha$ increases, the warm plasma effects yield a maximum in $|\theta(k_\perp)|$. For $\alpha=1$, $\theta(k_\perp)=0$, implying that inertial and warm plasma effects cancel each other. For $\alpha=1$, KA waves have peaked $\theta(k_\perp)$. Both regimes of propagation show that there is a maximum angle depending on $\alpha$. These maximum angles determine the maximum spreading of the wave power across $B_s$ as a wave structure, narrow across $B_s$, propagates along the magnetic field.

It is possible to determine the maximum group velocity angles in the IA and KA wave regimes. We find that in the IA regime, maximum value of $\theta$ is

$$\theta_{max} \sim -(\omega/\Omega_i)(m/M)^{1/2}/(1+\alpha), \quad \alpha^2 \ll 1$$

and it occurs for $k_\perp / \alpha^{1/2} > k_s$. For all other values of $k_\perp$, $\theta < \theta_{max}$. When $\alpha \rightarrow 0$, $\theta_{max}$ becomes the same as the Alfvén wave resonance cone found from cold plasma description (Singh, 1999). For the IA waves propagating along $\theta_{max}$, the parallel phase velocity ($V_{p||}$) and the ratio of transverse components of electric ($E$) to magnetic ($B$) fields are

$$V_{p||} \sim V_A\alpha/(1+\alpha) \sim \alpha V_A, \quad E/B \sim V_{p\perp} \sim \alpha V_A, \quad \alpha^2 \ll 1.$$  \hspace{1cm} (7)

Note that the ratio $E/B$ is often used to test whether waves observed from satellites are Alfvén waves or not. For the KA waves, we obtain maximum angle

$$\theta_{k_{max}} \sim -2/(27)^{1/2}(\omega/\Omega_i) (m/M)^{1/2}(\omega/\Omega_e)C_s N_A, \quad \alpha^2 > 1$$

and it occurs at $k_\perp \sim k_s/2^{1/2} \alpha < k_s$. In (8) $C_s$ is effective ion–acoustic speed defined by $C_s^2 = (0.75T_e + T_i)/M$.

3. Propagation within a cone from a narrow structure at large altitudes

A consequence of the group velocity vector making a small angle from $B_o$ in both IA and KA wave regime is that the wave power diverges across $B_s$ when launched from distant localized sources. This is schematically shown in Fig. 2.

The rate of divergence along the field line is

$$dX/ds \sim \tan(\theta) \sim \theta,$$  \hspace{1cm} (9)

where $X$ is the half-width of the wave structure at distance $s$ from the source at $r=r_s$. Using $\theta_{max}$ for IA waves and $\theta_{k_{max}}$ for the KA waves, the above equation can be integrated from $r=r_s$ to any altitude $r$ to yield the total width of the wave structure $W(r)$. For the KA waves, this integration might require numerical methods depending upon the electron and ion temperature profiles $T_e(r)$ and $T_i(r)$. For the IA waves, the integration is straightforward if one assumes that the plasma is dominated by $H^+$ over the altitude range of interest, and the magnetic field is given by $B(r)=B_e(R_e/r)^3$.

$$W(r) \sim 2X(r) = (1/2)(m/M_i)^{1/2}(\omega/\Omega_{i,c}) \left[ (r_s/R_e)^2 -(r/R_e)^4 \right] R_e,$$  \hspace{1cm} (10)

where $B_e$ and $\Omega_{i,c}$ are the earth’s magnetic field and ion cyclotron frequency at $r=R_e$, respectively. It is interesting to note, that (10) approaches an asymptotic limit when the height $z$ (Fig. 2) is sufficiently small so that $r(s)/R_e$ and $(r_s/r_i)^4 << 1$, giving the width

$$W \sim (1/2)(m/M_i)^{1/2}(\omega/\Omega_{i,c}) r_s.$$  \hspace{1cm} (11)
This is a constant width with variation in the altitude depending on electron to ion mass ratio, wave frequency and the source location \( r_s \) and it gives the absolute minimum latitudinal width; this is the transverse size of the IA wave when exited by an ideal line source at \( r=r_s \), with the latitudinal source width \( x_\theta \), like for a line source extending in longitude. If we assume a \( H^+ \) plasma we find that \( X(s)=5.8 \times 10^{-3} \left( \omega/\Omega_{he} \right) r_s \), and the transverse width \( W \) of an IA wave structure is

\[ W/R_e = 2X/R_e = 1.2 \times 10^{-2} \left( \omega/\Omega_{he} \right) (r/R_e)^4, \]

where \( \Omega_{he} \) is the \( H^+ \) ion cyclotron frequency at \( r=R_e \). If we assume \( r_s \approx 18R_e \) and \( \omega \approx 6.28 \text{ rad/s} \) (1 Hz), we find that 
\( W \approx 3 \text{ km} \) at ionospheric altitudes, comparable to the widths of narrow auroral arcs.

![Fig. 3. W(z) as a function of altitude z for \( r_s=11, 15 \) and 21 \( R_e \) when \( f=2 \) mHz. Note that \( W \) becomes asymptotically constant at lower altitudes in \( H^+ \) plasma.](image)

Fig. 3 shows \( W(z) \) as a function of \( z \) from (10) for three source locations \( r/R_e = 11, 15 \) and 21 when frequency \( f=2 \) mHz. Note that for sufficiently small \( z \) (\( r<<r_s \)), the curves for \( W \) become flat giving a constant width of the wave structure as noticed earlier (see (12)). For the altitudes of observations of IAWs by Polar (\( z \approx 3-4R_e \)), the widths range over 4-60 km as the source location varies from \( r_s=11 \) to 21 \( R_e \) when \( f=2 \) mHz. The constancy of \( W \) with \( r \) at sufficiently large distance from the source seen for the IA waves also holds good for the KA waves. This is more so because the cone angle \( \theta_{max}=B(r)^{\alpha} \) due to the factors \( \Omega_\alpha \) (\( \alpha \)) for the KA waves and \( V_\alpha \) (\( \alpha \)) being in the denominator of eqn. (8) for \( \theta_{max} \).

4. Application to satellite observations

The constancy of \( W \) has the following implications for the scaling of the Poynting flux (S). Wygant et al. suggest that
\( S=1-2 \text{ ergs cm}^{-2} \text{ s}^{-1} (1-2 \text{ mWatt/m}^2) \) at the altitude of measurements of IAWs by Polar and when mapped to ionospheric altitudes along converging magnetic field lines \( S=100 \text{ ergs cm}^{-2} \text{ s}^{-1} \) (0.1 Watt/m\(^2\)). In contrast, in view of the constant width of the narrow Alfvén wave structures with the decreasing altitude to the ionospheric heights the power flux must not increase directly with increasing \( B \). The increase might result only partially due to the convergence of \( B \) in longitude giving \( S \approx B^{1/2} \). Thus, in case of the Polar observation the power density at the ionospheric altitudes might just be 10 ergs cm\(^{-2}\) s\(^{-1}\), an order of magnitude smaller than suggested by (Wygant et al. 2000). We support this claim from two studies based on magnetic conjunction between Polar and FAST and Geotail and Polar.

Polar-FAST conjunction

We find that simultaneously measured maximum fluxes from Polar and FAST during the condition of magnetic conjunction along night-side auroral field lines support the scaling \( S \approx B^{1/2} \). The data is reported in Fig. 3 of (Dombeck et al. 2005). As normally done, Dombeck et al (2005) map the values \( S \) as measured by Polar and Fast to 100 km (1.06\( R_e \)) altitude in the ionosphere. At the time of the conjunction, geocentric distance of FAST and Polar are \( r_p=1.549R_e \) and \( r_p=7.1R_e \); the subscripts ‘p’ and ‘f’ refer to Polar and FAST, respectively. Thus the normal mapping amplifies measured \( S \) by a factor 300 for Polar and 3 for FAST. The mapped maximum fluxes at 5mHz from FAST and Polar are \( S_p=1 \) and \( S_p=10 \text{ mWatt/m}^2 \), giving actual wave energy fluxes at the satellites \( S_0(r=r_p)=0.33 \) and \( S_0(r=r_p)=0.033 \text{ mWatt/m}^2 \). Thus we find that actual fluxes at the satellites have a ratio \( S_p/S_p = (r_p/r_f)^{3/2} \approx 10 \), supporting our suggestion that \( S \approx B^{1/2} \) for narrow structure Alfvén waves.

Geotail-Polar conjunction

Angelopoulos et al. (2002) compared the Alfvén wave Poynting fluxes measured by Polar and Geotail during a magnetic conjunction. They report a peak flux \( S_p=0.23 \text{ mWatt/m}^2 \) during a wave event of extremely narrow Alfvén wave structure detected with full resolution from Geotail at \( r=18R_e \). The corresponding flux at Polar was \( S_p=1.25 \text{ mWatt/m}^2 \) at \( r=5R_e \). The unperturbed magnetic fields at the satellites are given as \( B_p=280 \text{ nT} \) and \( B_g=18 \text{ nT} \). Using the usual scaling \( S \approx B \), the measured flux at Geotail translates to \( 0.23 \times (280/18)^{1/2} \approx 3.6 \text{ mWatt/m}^2 \) at Polar. Thus there is a loss of 2.35 \text{ mWatt/m}^2 and it was attributed to the energization of electrons and ions in the intervening distance between the satellites. However, the flux balance was not demonstrated by including particle energy fluxes. In view of the latitudinal constancy of the widths of KA waves, the flux expected at Polar should be only \( 0.23 \times (280/18)^{1/2} \sim 1 \text{ mWatt/m}^2 \). In view of all the uncertainties in averaging of fluxes at the two satellites, this estimate seems to be in good agreement with the flux measured at Polar.

5. Conclusion

Our primary conclusion is that while mapping Poynting flux of dispersive Alfvén waves measured by high-altitude satellites to low altitudes, its divergence due to non-zero perpendicular group velocity must be properly accounted. It turns out that narrow Alfvén wave structures attain a constant width in latitude and therefore the convergence in \( S \) due to increasing \( B \) with decreasing \( r \) is given by \( S \approx B^{1/2} \) and not commonly used mapping \( S \approx B \).
